Abstract

Background: Limited health literacy makes decision-making difficult and has implications for individual health, costs, and the organization of health systems in general, and therefore must be studied in different communities, allowing an adequate response to the specificities, particularities, and potentialities of each local situation. **Methods:** To evaluate the level of health literacy and relate it to sociodemographic variables (sex, age group, education, and employment situation), this study was carried out in a population of 3,927 individuals from a parish of Alto Minho with a random probabilistic sample of 351 individuals, stratified by age and sex, with a sampling error of 5%. This is a quantitative, observational, and cross-sectional study. **Results:** The majority of respondents were female (54.1%), with a mean age (\pm SD) of 44.94 ± 19.048 years, had higher education qualifications (74.0%), and were professionally active (61.0%). The health

literacy of this community is limited (66.1%) in its different domains. In all of them, individuals assume easy and very easy activities that do not involve critical analysis and interpretation, and reveal greater difficulty in those that require this ability. Statistically significant relationships were found between the level of health literacy and schooling ($\chi^2 = 33.552$ and $p \leq 0.001$). **Conclusion:** This study allowed us to recognize that the health literacy level of this Alto Minho community is limited. Also, the fact that it is related to certain sociodemographic variables sheds light on the health literacy level of the people of this community and on the challenges of promoting it.

Resumo

Introdução: A Literacia em Saúde limitada condiciona os indivíduos nas suas decisões e acarreta implicações na saúde individual, nos custos e na organização dos sistemas de saúde em geral, pelo que urge o seu estudo em diferentes comunidades permitindo uma resposta adequada às especificidades, particularidades e potencialidades de cada realidade. **Métodos:** Com o objetivo de avaliar o nível de Literacia em Saúde e relacioná-lo com as variáveis sociodemográficas (sexo, grupo etário, escolaridade e situação face ao emprego), realizou-se este estudo numa população de 3,927 indivíduos de uma freguesia do Alto Minho com amostra probabilística aleatória, de 351 indivíduos, estratificada por idade e sexo, com um erro amostral de 5%. Trata-se de um estudo quantitativo, observacional analítico e transversal. **Resultados:** A maioria dos inquiridos é do sexo feminino (54.1%), com idade média \pm desvio padrão de 44.94 ± 19.048 anos, possui habilitações literárias superiores à escolaridade obrigatória (74.0%) e encontra-se em situação profissionalmente ativa (61.0%). A Literacia em Saúde desta comunidade é limitada (66.1%) nos seus diferentes domínios. Em todos eles os indivíduos assumem como fácil e muito fácil atividades que não envolvem análise crítica e interpretação e revelam maior dificuldade nas que exigem essa capacidade. Foi encontrada relação estatisticamente significativa do nível de Literacia em Saúde com a escolaridade ($\chi^2 = 33.552$ e $p \leq 0.001$). **Conclusão:** Este estudo permitiu conhecer o nível de LS desta comunidade do Alto Minho que se caracteriza como limitado. Também o facto de estar ou não relacionada com determinadas variáveis sociodemográficas permitiu a reflexão sobre a LS das pessoas desta comunidade e sobre os desafios da promoção da mesma.

Introduction

People's empowerment in relation to their own health is now one of the central goals in health at the European level [1], and in Portugal this is framed through strategies delimited in the National Health Plan [2] and in the Literacy Program in Health and Care Integration [3], materialized through the SNS + Proximity Project [4], among others. In these two programs the purpose is to promote the literacy and empowerment of citizens, making them more autonomous and responsible in relation to their own health and that of those who depend on them.

Studies of health literacy (HL) have been carried out in different countries, including in Portugal [5–7]. Nevertheless, it is important to study this in different smaller communities so that in-depth knowledge can enable health professionals to carry out interventions that are more adjusted to their local specificities. HL is understood as the “set of cognitive and social skills and the ability of individuals to understand and use information in order to promote and maintain good health” [8].

According to Nutbeam [9] HL can be functional, interactive, or critical. The level of functional HL is characterized by the presence of basic reading and writing abilities. The interactive aspect involves social capacities that allow the active participation and autonomous and preventive use of health care (HC). Finally, the critical HL level relates to the capacity for critical analysis of relevant information.

According to several studies [5, 10], a limited level of HL conditions individuals to make appropriate decisions. This limitation leads to a lower capacity for managing chronic diseases and low adherence to therapy, which will be reflected in an increase in hospitalization and rehospitalization rates, an increased morbidity rate, and premature death [9], with implications for the costs and organization of health and social systems [11].

Evidence of the cost-effectiveness of interventions to improve HL levels lacks research. A systematic review in 2009 showed that additional costs associated with limited HL levels can be substantial (3–5% of the total cost of HC) [11], but on the other hand it emphasized that some studies are inconclusive.

It is also urgent to investigate the influence of these determinants in different communities, in order to respond to the specificities, particularities, and potentialities of each community for an intervention adjusted to these realities. Here, health professionals with community intervention play a crucial role in empowering the individual to make conscious decisions about their habits, which generates autonomy for the continuous improvement of their health [12].

HL: Context

The World Health Organization [10], and some authors [13–15], present HL in different domains in the health context, focusing on access to HC, disease prevention (DP), and health promotion (HP). In turn, health-related information can be processed at the levels of access, understanding, evaluation, and its use/application.

Table 1. Matrix of the 12 HL subdimensions used by Espanha et al. [5]

HL	Access information relevant to health	Understand information relevant to health	Evaluate information relevant to health	Use information relevant to health
HC	Ability to access medical or clinical information	Ability to understand medical information and its meaning	Ability to evaluate medical information	Ability to make informed decisions in medical matters
DP	Ability to access information about risk factors	Ability to understand information about risk factors and their meaning	Ability to interpret information about risk factors	Ability to judge the relevance of risk factors
Health promotion	Ability to update health topics	Ability to understand information related to health and its meaning	Ability to interpret and evaluate health-related information	Ability to form mirrored information

The present study followed these conceptual assumptions.

At the intersection of the different domains and levels of information processing, we utilized a matrix with a total of 12 subdimensions for HL [16] (Table 1). Each domain comprises a number of questions that are converted into an index, with a standardized scale ranging from 0 to 50 (minimum and maximum of HL), using the following formula: $\text{index} = (\text{mean} - 1) \times (50/3)$, where “index” represents the calculated specific index, “mean” is the average of all the items marked by each individual in the different questions, “1” is the average minimum possible value, “3” is the average range, and “50” is chosen from the new metric [15].

After the analysis of the indexes, HL was categorized, according to the points obtained, into four levels: inadequate (0–25), problematic (26–33), sufficient (34–42), and excellent (43–50) [10, 13–15]. After this categorization, the inadequate and problematic levels were grouped into a single level, designated limited [15].

Fawcett et al. [17] identified some determinants of HL, namely education, personal skills, early child development, aging, living and working conditions, gender, culture, and language. In an Australian study, it was concluded that 59% of the population aged between 15 and 74 years has a level of HL that does not allow them to respond to the demands of their daily lives [16], with emphasis on elderly people of non-English origin (within an English-speaking society) and people with low literacy as groups of greater vulnerability.

In the study by Pedro et al. [6] on the translation and validation of the European Health Literacy Survey (HLS-EU) for the Portuguese population, a sample of 1,004 individuals was taken at national level, including individu-

als with limited HL. The subgroups with lower HL levels were: the elderly, the less educated, the unemployed, and the retired, all of which are considered vulnerable groups. The recognition of these groups is of enormous importance for health professionals, since knowing the HL level of subjects will enable them to adapt any and all interventions so that they are positioned and involved in the whole process.

Objectives

The present study was developed in the parish of Alto Minho and had the following objectives: (1) to assess the level of HL in this community, and (2) relate the HL level to sociodemographic variables (sex, age group, education, and employment situation).

Methods

This is a quantitative, observational, and cross-sectional study. The population selected for this study was 3,927 inhabitants in total, including 1,874 males and 2,053 females, representing a gender distribution that is identical to the Portuguese population [18]. Accordingly, respecting a fair population distribution, the sample was randomly probabilistically stratified by age and sex, through the sample size calculator da Raosoft®, with a maximum sampling error of 5%, obtaining a total sample of 351 individuals (161 males and 190 females), aged 15 years or older. Individuals with sensory-cognitive and mental deficits that precluded communication were excluded. Interview by questionnaire was the methodology used to collect data via a random itinerary in the choice of street, building, and building floor, providing a random selection of addresses [5].

Measure

The data collection instrument selected was the adapted version of the HLS-EU for the Portuguese population, of the National School of Public Health at the New University of Lisbon [5]. This questionnaire consists of 5 modules that evaluate: information and

Table 2. Sociodemographic characterization of the population sample ($n = 351$)

Variable	<i>n</i>	%	Medium (SD)	Min./max.
Sex				
Male	161	45.9		
Female	190	54.1		
Age group				
≤64 years	276	78.6	44.94 (19.048)	15/88
≥65 years	75	21.4		
Employment situation				
Active	214	61.0		
Inactive	137	39.0		
Schooling				
Without schooling, 1st and 2nd degree	90	25.6		
3rd degree and high school	170	48.4		
Higher education	91	25.9		

communication techniques and health, literacy, individual and family health perception, practices and attitudes in the field of HL, and sociodemographic characterization. Only two of these modules were used in the present study, namely module 5 (sociodemographic characterization) and module 1, which has a Cronbach alpha of 0.96 on the 47-issues scale (representing very good internal consistency, since it is higher than 0.920) [19] that assesses the complexity of the HL competencies of individuals, including users in need of HC, individuals at risk who are involved in prevention services, and citizens seeking to promote their health. The formula (see above) is used both for the general index (covering the 47 questions) and for the different subindices: HC index (question 1–16), DP index (question 17–31), and HP index (question 32–47) [15].

After data collection, statistical analysis was performed using SPSS software version 24.0. The sociodemographic characterization of the sample was undertaken through descriptive statistics, using absolute numbers and relative frequencies, means, and standard deviation (SD). The χ^2 test was used to evaluate the effect of sociodemographic variables on the different HL indexes, considering degrees of freedom and level of significance ($p = 0.05$).

Although we observed a significant effect of age group factors ($\chi^2 = 8.228$; $p = 0.016$) and schooling ($\chi^2 = 33.552$; $p \leq 0.001$) in the dependent variable, it was not possible to confirm the logistic regression model. A larger sample and greater variability of the data would have allowed for more significant results.

Results

The surveyed population had a predominant female profile (54.1%), aged between 15 and 88 years. The mean age (\pm SD) was 44.94 ± 19.048 years and the majority (61%) were professionally active (Table 2). Regarding HL, the internal consistency of the instrument in this sample assumed a behavior similar to that evidenced in the HL report in Portugal [12], with a Cronbach alpha of 0.97.

Table 3. HL levels of the community of Alto Minho within the different domains

	Level of HL					
	limited		sufficient		excellent	
	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%
General	232	66.1	95	27.1	24	6.8
HC	223	63.5	98	27.9	30	8.5
HP	250	71.2	65	18.5	36	10.3
DP	223	63.5	92	26.2	36	10.3

The parish of Alto Minho has a limited level of HL (66.1%), transverse to all subdimensions. In the HP subcategory, the proportion of individuals with limited HL was still higher (71.2%) and only 6.8% of individuals presented excellent HL (Table 3).

In the critical analysis of the 47 questions, it could be verified that the task considered the easiest by most respondents was “call an ambulance in case of emergency,” which represented 46.6% of answers.

In the access to HC field, more than 91% of respondents stated that “following instructions” (prescribed medication and medical or pharmaceutical indications) and the difficulty in evaluating “whether information on the disease in the media is reliable” (46.4%) are easy tasks. In the DP domain, the task considered the easiest was “understand why you need to do routine medical exams” (96.8%), and the most difficult was the “reliability assessment of information on health risks transmitted by the media of communication” (45.3%).

Table 4. HL levels according to the different sociodemographic variables

Variable	HL level, %			χ^2	Degrees of freedom	<i>p</i>
	limited	sufficient	excellent			
Sex						
Male	67.1	25.5	7.5	0.490	2	0.783
Female	65.3	28.4	6.3			
Age group						
15–24 years	64.3	28.9	6.8	5.488	4	0.241
25–64 years	63.8	25.5	10.6			
≥65 years	80.5	17.1	2.4			
Employment situation						
Active	65.0	28.5	6.5	0.598	2	0.742
Inactive	67.9	24.8	7.3			
Schooling						
Without schooling, 1st and 2nd degree	82.2	14.4	3.3	33.552	4	0.000
3rd degree and high school	68.8	27.1	4.1			
Higher education	45.1	39.6	15.4			

In HP, the easiest task was to “evaluate how housing conditions help you stay healthy” (88.7%). “Know more about changes in policies that may affect your health” (13.2%) was considered the most difficult in this area (and also in the overall index).

In relation to the sociodemographic variables with HL, it was verified that there is no statistical evidence to support the existence of a significant relationship between HL and gender, as well as the situation with regard to employment (Table 4).

In this community, HL does not seem to be influenced by age. The only determinant that seems to influence HL is schooling ($p < 0.01$). However, there remains a significant percentage of individuals with limited HL (11.7%; Table 4). We included the family income of the respondents as an indicator to determine whether or not it has a relationship with HL. However, a high percentage of respondents omitted this response and therefore it was not considered in the present analysis.

Discussion

A predominance of females is evident in national [6, 20, 21] and international studies [13, 21, 22]. Therefore, the greater number of females can be justified in our study by the fact that in the municipality where the study was conducted women represent more than 50% of the total population [23]. The age profile of this sample is compatible with international studies [11] and is in agreement

with the 66% of the population of this county aged between 15 and 64 years [24].

More than 74% of the sample has a literacy higher than compulsory schooling, which is in line with the 30.4% of the county’s population with secondary and higher education, although 10% are illiterate [23]. The limited level of HL (66.1%) in this parish is consistent with the findings of national studies [5, 7, 10, 15, 25, 26], with Portugal being below the European average according to the HL report in Portugal [5].

In all domains, individuals assume easy and very easy activities that incorporate functional HL, not involving critical analysis and interpretation of activity, and reveal greater difficulty in activities that require this capability. These results, according to the HL [5] report, should be read with caution, since considering a difficult or very difficult activity may manifest problems of literacy or greater attention and awareness of a certain difficulty given its complexity. This limitation will require professionals to readapt the way they work to create equal opportunities regardless of the individual’s HL level. If an individual has greater difficulty in analyzing and interpreting, it will be necessary to create simple strategies to transmit the information and to promote health.

The relationship between HL and employment still lacks research. The active population (employees and students), which interacts actively with systems, has higher HL levels than those who are not active (retired, unemployed, and domestic). These results are similar to those found in the HL report for Portugal [5].

This finding should be evaluated with special attention because inactive people are more likely to have comorbidities as they age. Thus, those who use the health system more often have a limited HL level, which may be a barrier to professional intervention [27, 28].

As far as gender is concerned, there is no agreement with the results obtained in several studies. Some Portuguese [15, 24, 29] and European studies [22] show that sex does not influence HL. On the one hand, in the comparative study of HL in eight European countries [13], a higher HL was observed in female subjects. Similar data were found in an e-Literacy study in youths/adolescents carried out in the city of Leiria [30]. On the other hand, in a study by Serrão et al. [25] involving 433 elderly Portuguese, male participants had higher levels of HL when compared to females.

The difference between studies with young people and studies with the elderly highlights the evolution of society. Today, contrary to the situation a few decades ago, women have equal access to education, which may explain the inexistence of a relationship between the gender and HL in this community of Alto Minho.

Although in the present study there was no statistically significant relationship between HL and age, this has been demonstrated in several national [5, 15, 29, 30] and international studies [13, 22, 31]. In the HL report [5], it is highlighted that “in all domains there is a transversal relation between the increase of the age of the individuals and the increase of the limitations in the accomplishment of tasks related to the HL.” However, we highlight the study by Marques [14], in which there is no relationship between HL and age. With increasing age a smaller percentage of individuals with sufficient and excellent HL can be observed. This is a relevant fact, since it is with the advancement of years that many chronic diseases arise and there is evidence that limited HL is associated with worse health outcomes and also an inadequate use of health services [11].

HL also seems to be influenced by education, with individuals with higher levels of schooling having the highest levels of HL; however, a significant percentage (11.7%) of individuals with limited HL cannot be neglected. Although this finding has been corroborated by several authors [5, 13, 29], there are also studies in which there is no relationship between these variables [5].

In a district where 10.7% of the population is illiterate, 75.6% have 9th grade and 14.2% higher education (there has been a 98% increase in people with this school level in last decade) [23]. Thus, the greater weight of the population has a level of schooling to which a smaller percentage of limited HL should correspond.

Conclusion

With this work we intend to offer a small and innovative contribution in the understanding of what is understood and encompasses HL. Although they cannot be extrapolated to the general population, the results of this study allowed us to determine the HL level of this Alto Minho community, which is characterized as limited. Also, the fact that it is related to certain sociodemographic variables has shed light upon the HL of the people of this community and on the challenges of promoting it, which together can be proposed for the development of good practices, namely access to information and lifelong learning opportunities.

Faced with a community with limited HL, it is necessary to carry out new studies that analyze the existence of a relationship between socioeconomic variables and HL in different communities, with a view to the intervention of health teams in individual, social, and cultural contexts, in the direction of its promotion.

Acknowledgments

We would like to thank Cátia Barbosa, Celsa Ferros, and Susana Evangelista for their help in the design of and data collection for the present study, and the entire population of Alto Minho for their receptivity and collaboration.
